# A Scale for Markets and Property in the Societies of the Standard CrossCultural Sample: a Linear Programming Approach ${ }^{1}$ 

E. Anthon Eff *<br>Middle Tennessee State University, Murfreesboro, TN

#### Abstract

Cross-cultural researchers often combine several component variables into a composite index or "scale." The value of a scale for a particular observation is sensitive not only to the values of its component variables, but also to the values of the weights used to combine the components. This sensitivity to weight values is unfortunate, given that the choice of weighting scheme is in some ways arbitrary. A method is presented here, based on linear programming, which reduces the sensitivity of a scale to the component weights. An example scale is produced, for the prevalence of markets and property rights in the societies of the Standard Cross-Cultural Sample. A program, written for R , is included.

Key words: Standard cross-cultural sample; linear programming; Tiered Data Envelopment Analysis; market and property rights index

JEL category: Z13, C6

[^0][^1]
## I. Introduction

Cross-cultural researchers often produce "scales" in which the values of several variables are combined into a composite index. In the Standard Cross-Cultural Sample (SCCS), a scale is most often simply the sum of the component variables as, for example, the cultural complexity scale formed by summing variables 149 through 158 (Murdock and Provost 1971); the pathogen stress scale (variable 1260) formed by adding variables 1253 through 1259 (Low 1988); and the modernization scale (variable 1849) created by summing variables 1806 through 1838 (Divale and Seda 2000). Other scales are produced using factor analysis, such as the factors produced on the gossip-related variables 1781-1805 (Divale and Seda 1999).

Scales created by summing component variables, by principal components analysis, or by factor analysis are all examples of composite indices, in which the values of component variables are combined into a single ordinal scale. A composite index, in its most general form, is the weighted sum of the component variables:

$$
\begin{equation*}
\theta_{i}=\sum_{r=1}^{p} y_{r i} \mu_{r}, \forall i \tag{1}
\end{equation*}
$$

where the value of the index for society $i\left(\theta_{i}\right)$ is the sum of the component variable values $\left(y_{r i}\right)$ for $p$ components, each component value weighted by a weight $\left(\mu_{r}\right)$. The component variables are almost always first scaled similarly, typically by standardizing or converting to ranks. A wide variety of methods exist for specifying the weights $\mu_{r}$, and in most cases, there is no a priori reason to choose one weighting scheme over another. The choice of weights can therefore often be criticized as arbitrary.

## <Figure 1 about here>

Figure 1a presents a scatter plot of two component variables for 20 societies. Note that society $A$ has a low value for component 1 but a very high value for component 2 . Society $T$ is in the opposite situation: a very high value for component 1 but a low value for component 2 . A would rank highest with high weights on component 2 , and $T$ would rank highest with high weights on component 1 . Both of these
societies would rank relatively low when using equal weights on each component, a scheme which would cause societies $O$ and $Q$ to rank quite high. One can see, then, that changes in weights can lead to large changes in the overall index.

## II. Proposed method

Ideally, one would wish for a method that diminishes the effect of weight choice in ranking societies. The method we describe here does just that: it separates societies into groups, such that the between-group differences in index rank are based solely on data values $\left(y_{r}\right)$, not on weights $\left(\mu_{r}\right)$. The method employs linear programming, solving for weights on the individual components $\left(\mu_{r}\right)$ in order to calculate the highest possible index for the $k^{\text {th }}$ society:

$$
\begin{array}{ll}
\text { Maximize } & \theta_{k}=\sum_{r=1}^{p} y_{r k} \mu_{r} \\
\text { Subject to } & \sum_{r=1}^{p} y_{r i} \mu_{r} \leq 1, \forall i \\
& \mu_{r} \geq 0, \forall r \tag{2.c}
\end{array}
$$

The constrained maximization problem in equations (2.a)-(2.c) is solved $n$ times-once for each of the $n$ societies. The objective function (2.a) selects weights in order to maximize the index score of the $k^{\text {th }}$ society. Constraint (2.b), however, restricts the weights so that-applied to every one of the $n$ societiesno society has a score higher than one. Thus, the highest value that the objective function may take is one - in such a case, the society will lie on the frontier shown in Figure 1a. In all other cases, the value of the objective function will be less than one, since the weights that maximize its own score give another society a score of one. Society $S$ 's index score, for example, would equal the solid portion of the ray on which it lies, divided by the total length of the ray below the frontier.

The difference between the frontier and the below-frontier societies is not caused by weights, since there exists no set of weights which can make the below-frontier societies the peers of the frontier societies.

Thus, finding a frontier to which each society belongs (as in Figure 1b) would be a way of grouping societies into subsets within which differences in index values can be removed by weight adjustment, and between which differences in index values cannot be removed by adjusting weights. This property is attractive, since it allows us to construct an index, consisting of the order of a society's frontier (as in Figure 1b), whose values are not determined by an arbitrary choice of weights.

In practice, one would usually choose to replace the zero in constraint (2.c) with a very small positive number, so that all component variables are considered when computing the optimum. The larger the constraint level, the greater the number of frontiers that will be generated. One might also add a constraint so that the shares of all component variables in the optimum exceed a certain threshold (Pedraja, et al. 1997).

This method of creating composite indices is closely related to the operations research procedure called Tiered Data Envelopment Analysis (TDEA) (Barr, et al. 2000), based on the widely used efficiency analysis technique Data Envelopment Analysis (Charnes, et al. 1978). Whereas TDEA is used to maximize an efficiency ratio of outputs over inputs, the present method in effect maximizes only the numerator of the efficiency ratio (the outputs). This numerator-only method has previously been used for ranking entities such as elementary schools (Eff 2004), universities (Bougnol and Dulá 2006), and U.S. states (Eff and Eff 2007).

## III. A scale for markets and property

As an example of this method, a scale is created for the prevalence of markets and property rights for the 186 societies in the SCCS. Descriptive statistics for the seven component variables selected are given in Table 1; the Pearson correlation coefficients in Table 2; and the SCCS codebook entries for each of these in Appendix 1.

The large number of missing values in the SCCS makes it prudent to use multiple imputation (Dow and Eff 2009a, 2009b; Eff and Dow 2009). Accordingly 10 imputed data sets are created, each data set containing the seven component variables, with missing values replaced by imputed values. A scale is computed separately for each of the 10 imputed data sets.

The seven component variables are selected from a larger number which plausibly provide some measure of the prevalence of markets and property rights. Unlike scales based on shared variation, candidate variables for the TDEA scale need not be strongly correlated with each other-the suitability of a candidate variable is determined conceptually ("does this variable measure some dimension of what this scale tries to capture?") rather than empirically ("does this variable correlate strongly with the other variables?"). Thus, for example, TDEA rankings of secondary schools might include component variables that are nearly orthogonal with each other, such as academic scores and the performance of sports teams. Despite the lack of shared variation, these nearly orthogonal variables measure valid dimensions of what one would consider a high school's performance, and so are conceptually sound choices for component variables.

Nevertheless, most scales used in cross-cultural research would in fact contain component variables that correlate consistently with each other-that is, the correlations of a component with other components would all be of the same sign and usually significant. From Table 2, one can see that the seven selected variables all have consistently signed correlations, though the Cronbach's alpha (0.653) would be considered a little low for scales based on shared variation, such as principal components or factor analysis. In fact, one can imagine that factor analysis might produce two latent variables from these seven component variables: one for markets, another for property. A virtue of the TDEA approach is that separate, but related, dimensions can be combined into a composite index.

## An $R$ program

Appendix 2 presents an R program that creates 10 imputed data sets and then calculates the scale for each set of data. The program, as well as the two data files it calls, is available online, in a zip folder. ${ }^{2}$ The user should unzip the zip folder, and change the working directory in the R program to the name of the folder where the zip folder was unzipped.

Higher values for each variable should have similar conceptual meanings. In this case, higher values should all indicate greater development of property rights and markets. As Table 2 shows, one of our variables (v1726) correlates negatively with the remaining six: higher values indicate less private property, not more. This variable is therefore multiplied by negative one, to ensure that it varies directly with the others.

Ten imputed data sets are created, using the auxiliary data set described in Eff and Dow (2009). All seven component variables are then standardized, with a mean of 100 and a standard deviation of 15 , so that no values are negative. The standardizations are performed separately within each of 10 imputed data sets.

The following section of code executes a series of nested loops, finding the optimal weights for each society, one imputed data set at a time. Within each imputed data set, any society reaching the frontier is removed from the set of comparison societies, until all societies have been removed. The order of removal indicates a society's rank, and is recorded as the field iter in the dataframe $s x$. The order of removal is then inverted to create the desired scale: sx\$iter<-(max (sx\$iter)+1)-sx\$iter.

Two output files are produced. The file $R \_W C t a b l e . c s v$ presents a table of the results, with society names, so that one can look over the rankings in a spreadsheet. The file findat. Rdata arranges the data so that it can be most easily used in a regression, using the programs given in Eff and Dow (2009).

[^2]The program sets the minimum weight size in constraint (2.c) to one-millionth, in the line reading $\operatorname{bvec}[1: N R O W(f c)]<-\left(1 / 10^{\wedge} 6\right)$. Were one to set this level to an even smaller number, fewer discrete values would appear in the final scale. For the current example, a minimum weight size of onebillionth returned six discrete values; a size of one-trillionth returned three discrete values.

Appendix 3 shows the values for the scale for each of the 10 imputations, sorted in ascending order for the society mean. The table is presented simply to show that the resulting scale seems reasonable, given the societies that rank low and high. The mean scale should not be used in a regression analysis, since it contains imputed values; a regression analysis should be conducted on each of the imputed data sets, and the results combined, as shown in Dow and Eff (2009a, 2009b) and in Eff and Dow (2009).

When the component variables are highly correlated with each other, the TDEA scale will be quite similar to the first principal component of the variables. Since the first principal component in such cases will have nearly equal weights on each of the variables, the mean or sum of the variables would also correlate quite highly with the first principal component (since these are also equal-weight indices). For our market and property index, with moderate correlation among the seven variables, the first principal component and the mean are practically identical, with a correlation of 0.992 . The correlation between the TDEA scale and these two measures is about 0.793 -quite high, but still different. This shows that allowing weights to vary, so as to group societies for which weight adjustments suffice to produce identical outcomes, leads to non-trivial differences in the ordinal ranking of societies.

## IV. Summary

The scales often used by cross-cultural researchers are weighted sums of component variables. Different choices of weights will produce different rank orderings of societies. The method presented here reduces the sensitivity of the scale to the weights chosen, by classifying together societies for whom adjustments in weights give an equally high rank.

The method is particularly suitable for cases where weakly correlated or orthogonal variables are combined into a scale. For example, variables for internal war and external war (Ember and Ember 1992) could be combined into a scale for the prevalence of war.

The R program given in Appendix 2 creates a scale for the prevalence of markets and property rights in the 186 societies of the SCCS, using the seven component variables shown in Appendix 1. Since multiple imputation offers the best approach for using the SCCS (Dow and Eff 2009a, 2009b), the program creates the scale for each of 10 imputed data sets. With suitable modifications, the program can be used to produce any scale for SCCS data.

| v1734 | 0.21 | -0.14 | 0.14 | 0.22 | 1.00 | 0.11 | 0.20 | 0.29 |
| v278 | 0.42 | -0.31 | 0.14 | 0.11 | 0.11 | 1.00 | 0.42 | 0.36 |
| v279 | 0.29 | -0.13 | 0.24 | 0.17 | 0.20 | 0.42 | 1.00 | 0.35 |

Notes: Variable labels given in Table 1. "mnAbs" is the mean of the absolute values of the row correlation coefficients.

Figure 1: The values of two component variables are plotted for twenty societies. Linear programming is used to wrap a convex frontier around the cloud of points; societies on the frontier are tied for the highest composite score, while societies below the frontier have a score given by their location as the proportion of the distance from the origin to the frontier. The tiered frontiers method draws a series of successive convex frontiers, classifying each society into a peer group, based on the values of the component variables. The order of the frontier is then used as an index.
